Developmental programs are controlled by transcription factors and chromatin regulators, which maintain specific gene expression programs through epigenetic modification of the genome. These regulatory events at enhancers contribute to the specific gene expression programs that determine cell state and the potential for differentiation into new cell types. Although enhancer elements are known to be associated with certain histone modifications and transcription factors, the relationship of these modifications to gene expression and developmental state has not been clearly defined. Here we interrogate the epigenetic landscape of enhancer elements in embryonic stem cells and several adult tissues in the mouse. We find that histone H3K27ac distinguishes active enhancers from inactive/poised enhancer elements containing H3K4me1 alone. This indicates that the amount of actively used enhancers is lower than previously anticipated. Furthermore, poised enhancer networks provide clues to unrealized developmental programs. Finally, we show that enhancers are reset during nuclear reprogramming.

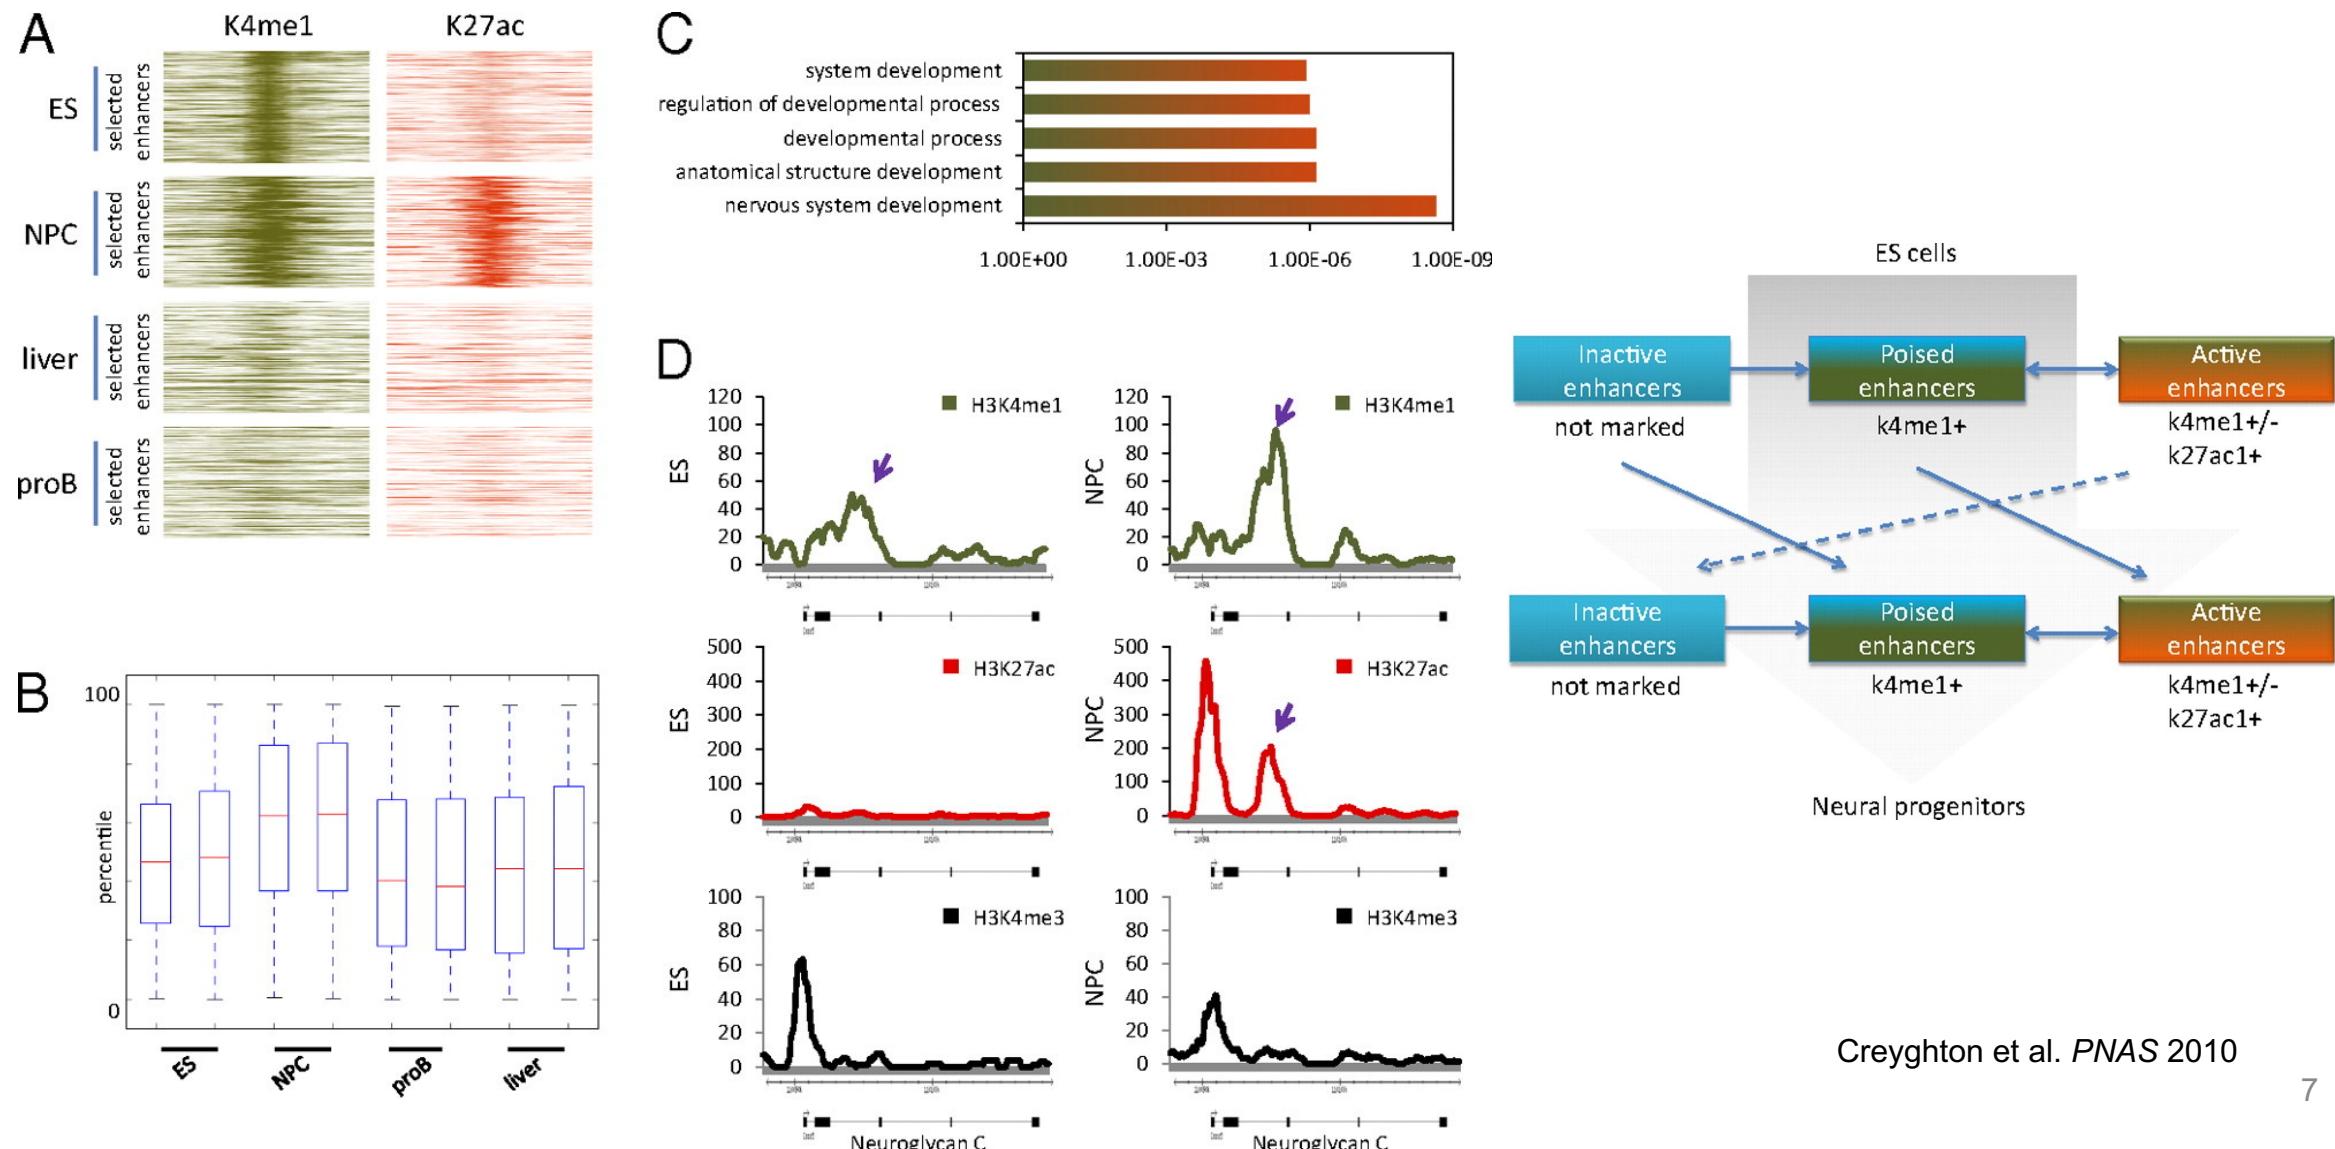

distal enhancers (13). Finally distal H3K4me1-enriched Stat1 binding sites become selectively activated upon INF- γ treatment of HeLa cells, suggesting that these regions maintain the potential to become active (5). This raises the intriguing possibility that enhancers contain information about the current and future developmental potential of a cell, as well as its ability to respond to external cues.

Here, we identify close to 135,000 candidate distal enhancer regions in five different cell types. In a candidate approach to identify factors that could potentially discriminate between the various possible enhancer states, we establish H3K27ac as an important enhancer mark that can distinguish between active and poised enhancer elements. This mark can be deposited by both p300 and CREB binding protein (CBP) (14) and is associated with active promoters in mammalian cells (15). Using this modification to distinguish poised from active enhancer networks allows us to make predictions on the developmental potency of the cell, as well as its current state. Furthermore, it suggests that the active global enhancer network of a cell is smaller than previously anticipated.

SUMMARY

Master transcription factors Oct4, Sox2, and Nanog bind enhancer elements and recruit Mediator to activate much of the gene expression program of pluripotent embryonic stem cells (ESCs). We report here that the ESC master transcription factors form unusual enhancer domains at most genes that control the pluripotent state. These domains, which we call super-enhancers, consist of clusters of enhancers that are densely occupied by the master regulators and Mediator. Super-enhancers differ from typical enhancers in size, transcription factor density and content, ability to activate transcription, and sensitivity to perturbation. Reduced levels of Oct4 or Mediator cause preferential loss of expression of super-enhancer-associated genes relative to other genes, suggesting how changes in gene expression programs might be accomplished during development. In other more differentiated cells, super-enhancers containing cell-type-specific master transcription factors are also found at genes that define cell identity. Super-enhancers thus play key roles in the control of mammalian cell identity.

INTRODUCTION

Transcription factors typically regulate gene expression by binding cis-acting regulatory elements known as enhancers and by recruiting coactivators and RNA polymerase II (RNA Pol II) to target genes (Lelli et al., 2012; Ong and Corces, 2011). Enhancers are segments of DNA that are generally a few hundred base pairs in length and are typically occupied by multiple transcription factors (Carey, 1998; Levine and Tijan, 2003; Panne, 2008; Spitz and Furlong, 2012).

Much of the transcriptional control of mammalian development is due to the diverse activity of transcription-factor-bound enhancers that control cell-type-specific patterns of gene

expression (Bulger and Groudine, 2011; Hawrylycz et al., 2012; Maston et al., 2006). Between 400,000 and 1.4 million putative enhancers have been identified in the mammalian genome by using a variety of high-throughput techniques that detect features of enhancers such as specific histone modifications (Dunham et al., 2012; Thurman et al., 2012). The number of enhancers that are active in any one cell type has been estimated to be in the tens of thousands, and enhancer activity is largely cell-type specific (Dunham et al., 2012; Heintzman et al., 2009; Shen et al., 2012; Visel et al., 2009; Yip et al., 2012).

In embryonic stem cells (ESCs), control of the gene expression program that establishes and maintains ESC state is dependent on a remarkably small number of master transcription factors (Ng and Surani, 2011; Orkin and Hescheler, 2011; Young, 2011). These transcription factors, which include Oct4, Sox2, and Nanog (OSN), bind to enhancers together with the Mediator coactivator complex (Kagey et al., 2010). The Mediator complex facilitates the ability of enhancer-bound transcription factors to recruit RNA Pol II to the promoters of target genes (Borggreve and Yue, 2011; Conaway and Conaway, 2011; Komberg, 2005; Malik and Roeder, 2010) and is essential for maintenance of ESC state and embryonic development (Ito et al., 2000; Kagey et al., 2010; Risley et al., 2010).

ESCs are highly sensitive to reduced levels of Mediator. Indeed, reductions in the levels of many subunits of Mediator cause the same rapid loss of ESC-specific gene expression as loss of Oct4 and other master transcription factors (Kagey et al., 2010). It is unclear why reduced levels of Mediator, a general coactivator, can phenocopy the effects of reduced levels of Oct4 in ESCs.

Interest in further understanding the importance of Mediator in ESCs led us to further investigate enhancers bound by the master transcription factors and Mediator in these cells. We found that much of enhancer-associated Mediator occupies exceptionally large enhancer domains and that these domains are associated with genes that play prominent roles in ESC biology. These large domains, or super-enhancers, were found to contain high levels of the key ESC transcription factors Oct4, Sox2, Nanog, Klf4, and Esrrb to stimulate higher transcriptional activity than typical enhancers and to be exceptionally sensitive to

Selective Inhibition of Tumor Oncogenes by Disruption of Super-Enhancers

SUMMARY

Chromatin regulators have become attractive targets for cancer therapy, but it is unclear why inhibition of these ubiquitous regulators should have gene-specific effects in tumor cells. Here, we investigate how inhibition of the widely expressed transcriptional coactivator BRD4 leads to selective inhibition of the MYC oncogene in multiple myeloma (MM). BRD4 and Mediator were found to co-occupy thousands of enhancers associated with active genes. They also co-occupied a small set of exceptionally large super-enhancers associated with genes that feature prominently in MM biology, including the MYC oncogene. Treatment of MM tumor cells with the BET-bromodomain inhibitor JQ1 led to preferential loss of BRD4 at super-enhancers and consequent transcription elongation defects that preferentially impacted genes with super-enhancers, including MYC. Super-enhancers were found at key oncogenic drivers in many other tumor cells. These observations have implications for the discovery of cancer therapeutics directed at components of super-enhancers in diverse tumor types.

INTRODUCTION

Chromatin regulators are attractive as therapeutic targets for cancer because they are deregulated in numerous cancers (Baylin and Jones, 2011; Elsässer et al., 2011; Esteller, 2008; Feinberg and Tycko, 2004; You and Jones, 2012) and are amenable to small-molecule inhibition (Cole, 2008; Dawson and Kouzarides, 2012; Geutjes et al., 2012). Inhibition of some chromatin

SUMMARY

Super-enhancers are large clusters of transcriptional enhancers that drive expression of genes that define cell identity. Improved understanding of the roles that super-enhancers play in biology would be afforded by knowing the constellation of factors that constitute these domains and by identifying super-enhancers across the spectrum of human cell types. We describe here the population of transcription factors, cofactors, chromatin regulators, and transcription apparatus occupying super-enhancers in embryonic stem cells and evidence that super-enhancers are highly transcribed. We produce a catalog of super-enhancers in a broad range of human cell types and find that super-enhancers associate with genes that control and define the biology of these cells. Interestingly, disease-associated variation is especially enriched in the super-enhancers of ESCs. Similarly, it would be useful to know if super-enhancers are transcribed, as enhancer RNAs (eRNAs) have been proposed to contribute to enhancer activity (Lai et al., 2013; Lam et al., 2013; Li et al., 2013; Ling et al., 2004; Mousavi et al., 2013; Ormon et al., 2010).

Super-enhancers are associated with key genes that control cell state in cells where they have been identified thus far, so identification of these domains in additional cell types could provide a valuable resource for further study of cellular control. We have generated a catalog of super-enhancers in 66 human cell and tissue types. These super-enhancers are associated with genes encoding cell-type-specific transcription factors and thus identify candidate master transcription factors for many cell types that should prove useful for further understanding transcriptional control of cell state and for reprogramming studies. Using this catalog, we find that DNA sequence variation associated with specific diseases is especially enriched in the super-enhancers of disease-relevant cells, suggesting that hypotheses regarding the role of specific cell types and genes in many diseases might be guided by knowledge of super-enhancers. Furthermore, tumor cells acquire super-enhancers at key oncogenes and at genes that function in the acquisition of hallmark capabilities in cancer, suggesting that these domains provide biomarkers for tumor-specific pathologies that may be valuable for diagnosis and therapeutic intervention.

Transcription factors bind DNA regulatory elements called enhancers, which play key roles in the control of cell-type-specific gene expression programs (Bulger and Groudine, 2011; Calo and Wysocka, 2013; Carey, 1998; Lelli et al., 2012; Levine and Tijan, 2003; Maston et al., 2006; Ong and Corces, 2011; Parne, 2008; Spitz and Furlong, 2012; Xie and Ren, 2013). A typical mammalian cell contains thousands of active enhancers, and it has been estimated that there may be ~1 million enhancers active in all human cells (Berezin et al., 2012; Heintzman et al., 2009; Thurman et al., 2012). It is important to further understand enhancers and their components because they control specific gene expression programs, and much disease-associated sequence variation occurs in these regulatory elements

Chromatin-based functional genomic analyses and genome-wide association studies (GWASs) together implicate enhancers as critical elements influencing gene expression and risk for common diseases. Here, we performed systematic chromatin and transcriptome profiling in human pancreatic islets. Integrated analysis of islet data with those from nine cell types identified specific and significant enrichment of type 2 diabetes and related quantitative trait GWAS variants in islet enhancers. Our integrated chromatin maps reveal that most enhancers are short (median = 0.8 kb). Each cell type also contains a substantial number of more extended (≥ 3 kb) enhancers. Interestingly, these stretch enhancers are often tissue-specific and overlap locus control regions, suggesting that they are important chromatin regulatory beacons. Indeed, we show that (i) tissue specificity of enhancers and nearby gene expression increase with enhancer length; (ii) neighborhoods containing stretch enhancers are enriched for important cell type-specific genes; and (iii) GWAS variants associated with traits relevant to a particular cell type are more enriched in stretch enhancers compared with short enhancers. Reporter constructs containing stretch enhancer sequences exhibited tissue-specific activity in cell culture experiments and in transgenic mice. These results suggest that stretch enhancers are critical chromatin elements for coordinating cell type-specific regulatory programs and that sequence variation in stretch enhancers affects risk of major common human diseases.

DNA Elements (ENCODE) cell types to generate consistent chromatin state assignments across all 10 cell types. We anchored these assignments based on overlap with previously published chromatin states (2) in the nine ENCODE cell types to produce a consistent annotation of promoter, enhancer, insulator, transcribed, and repressed chromatin states (SI Appendix, Fig. S1). In parallel, we integrated our human islet RNA-seq data with ENCODE RNA-seq data, resulting in a unified set of chromatin state and mRNA maps for islets and the nine ENCODE cell types (Fig. 1A). After subsampling to normalize the amount of ChIP-seq reads, the fraction of the genome covered by select chromatin states remained relatively constant across any given cell type (Fig. 1B, Upper). However, we observed that additional read depth identified additional signal-enriched enhancer regions (SI Appendix, Fig. S2), a finding consistent with other studies (10, 11). Thus, in subsequent analyses, we used chromatin states identified using all reads (Fig. 1B, Lower) and note that the trends reported herein are consistently observed even when normalized read chromatin states are used. As shown in Fig. 1A, our integrative approach identified both common (e.g.,
